

# Decision tree: Crossing between rasters and vectors

## **st\_transform() then vect()**

crop() stops on a CRS mismatch, mask() warns and returns all NA, and extract() transforms silently: settle the CRS first

then

What does the question need?

a raster trimmed to the vector

## **crop(x, v)**

cuts the raster to the bounding box of the vector, so the grid gets smaller; mask = TRUE also sets the cells outside the vector to NA

a raster with the outside blanked

## **mask(x, v)**

sets the cells outside the vector to NA and leaves the grid where it was, so the extent does not change

raster values at vector locations

## **terra::extract()**

one row per point, in the order of the points; every covered cell for a polygon, unless fun summarizes them

a vector written onto a grid

## **rasterize()**

field sets what a cell holds, fun summarizes the features that fall in one, and background sets the rest

features from a raster

## **as.polygons() then st\_as\_sf()**

dissolves the cells of each class into one multipolygon, whose boundaries are cell edges rather than real ones
